

Define and document methods for producing projections; provide justification for assumptions of fishery selectivity, fecundity, mortality and recruitment; comment on the reliability of resulting projections considering the effects of uncertainty and sensitivity to projection assumptions. Compare the results of SAMS and GeoSAMS and comment on their appropriateness for use in management.

- Resource divided into subareas (currently 24 subareas: 7 in MA, 12 in GB and 5 in GOM)
- Population dynamics is similar to CASA model but is computed separately in each subarea, each with their own life history parameters.
- Populations are initialized based on most recent surveys
- Can be used to simulate area management such as closure and reopening
- Has been used in management since 1999

Current Mid-Atlantic and Georges Bank areas used in SAMS

Realized projection error

Mid-Atlantic has consistently overestimated biomass, likely due to underestimation of M and overestimated recruitment. This is also seen for Georges Bank, but to a much lesser extent; this may be fixed in part by the increase in M .

- Population dynamics occurs at each survey location from the initial year
- Population is projected forward, similar to SAMS, and then one a year, (exploitable) biomass and abundance are interpolated using regression kriging, similar to that used for Habcam.
- GEOSAMS is currently on hold due to funding issues
